Comment on the Relevance of Phosphorus and Sulfur 3d Orbitals

Edgar Müller*

Since the times of Valence Bond (VB) theory, which assigned a 2-electron orbital to each chemical bond, textbooks on phosphorus and sulfur [1] often emphasize the importance of the empty 3d orbitals on these elements, in an attempt to rationalize the differences between them and their corresponding first-row homologues. Noteworthy features, displayed by the second-row elements, include:

- 1) *Hypervalence* (i.e., the easy formation of PR_5 , PR_6 , SR_5 , and SR_6 compounds while the agreed 'maximal valence', according to the octet rule, would be four),
- 2) Softness of P- and S-ligands, compared to their N- and O-homologues: π -acidity, back-bonding, stabilization of carbanions at phosphorus or sulfur atoms (*Wittig* reagents).

In the framework of the VB formalism [2], both features are 'explained' with the help of *spd-hybrid* orbitals. Specifically, sp^3d hybrids are invoked for trigonal bipyramidal geometries at P, and sp^3d^2 hybrids for octahedral geometries at S [3]. The VB theory, which offered a theoretical justification for the organic chemist's intuitive and experimentally founded concept of valence [4], falls, however, short in explaining chemical bonding in a more general context. Phenomena like electron-deficient cluster bonds or solid-state metallic bonds are definitely out of its range;

they require a molecular orbital (MO) treatment. Even the organic chemist's familiar concepts of sp , sp^2 , and sp^3 -hybridized C-atoms cannot be maintained in the light of quantum physics: it is in fact possible to make four equal chemical bonds out of three p orbitals alone; the s orbital is not really needed! The only requirement is, that the symmetry of the coordination geometry (tetrahedral in this case) coincides with the symmetry of the electron cloud, as a corollary of the *Jahn-Teller* theorem. The experimental fact that ESCA spectroscopy yields **two** valence-shell ionization peaks at two different energies for ' sp^3 ' methane (corresponding to the carbon p- and s-shell ionizations, respectively) [5], can be viewed as a decisive **disproof** of the VB formalism, which, in turn, would predict only one such peak in this case. The localized sp^3 -hybrid orbitals, although obtained by a unitarian transformation from the atomic (s,p) basis orbital set, are no longer stationary solutions of the molecular *Schrödinger* equation; to all evidence, these hybrid orbitals are coupled together by the electron-electron repulsion operator, and a rediagonalization splits them up again into s and p waves!

The substitution of the chemically founded, ambiguous concept of *valence* by the better defined concepts of *oxidation state* ('main valence') and *coordination number* ('secondary valence') was first effected by A. *Werner* in his 'Neuere Anschauungen auf dem Gebiete der Anorganischen Chemie' [6], and has opened the way for a rapid rationalization of all aspects of inorganic chemistry after the advent of quantum mechanics. In the field of organic chemistry, however, the conventional valence concept kept much longer alive, as it apparently did a good job in almost all of the known cases [7].

The VB formalism in organic chemistry got furthermore an unexpected boost by the popularization of R. *Hoffmann's* extended *Hückel* method [8], where additional d functions in the basis orbital sets of the elements Si, P, S, and Cl turned out to improve the results substantially [9]. Had not MO theory finally joined the chemist's intuitional view, that elements which show more than four conventional valencies must also have more than four available 2-electron orbitals?

The answer to this question is given by a series of *Herman-Skillman* atomic struc-

Table 1. Conventional ICON Parameterization for Si, P, S, and Cl [14]

	ζ_s, ζ_p	ζ_d	E_s [eV]	E_p [eV]	E_d [eV]
Si	1.383	1.383	-17.3	-9.2	-6.0
P	1.600	1.400	-18.6	-14.0	-7.0
S	1.817	1.500	-20.0	-13.3	-8.0
Cl	2.033	2.033	-30.0	-15.0	-9.0

ture calculations [10] for the elements Si to Ti, including the 8 orbitals 1s, 2s, 2p, 3s, 3p, 3d, 4s, and 4p (Table 1). These calculations represent spherically and spin averaged values for the indicated (n,l) electronic configurations, and may be taken as a picture of the atom's situation in a closed-shell molecular environment [11].

The results of these calculations show that the 3d orbitals are throughout energetically high-lying ($E \approx -1.5$ eV) and diffuse (Slater-zeta = 0.35) orbitals for the elements Si to Ar. Their contribution to bonding is thus small [12]. It is noteworthy that the energies of the 4s and 4p orbitals lie throughout below the energies of the 3d shell (-2.9 to -3.7 eV and -2.0 to -2.5 eV, respectively) and that the 4s and 4p orbitals are much less diffuse (Slater-zetas = 0.61-0.75 and 0.47-0.58, respectively) than the 3d orbitals. If higher-lying atomic orbitals were to play a role in the chemistry of Si, P, S, and Cl, one had thus first to look about the 4s and 4p orbitals!

Potassium is the very first element, where the 3d orbitals may play a chemical role. In the K^+ ion, the 3d orbitals lie merely 2.3 eV above the 4s orbital and have very similar Slater-zeta values. For calcium, the empty 3d orbitals fall already below the 4s orbital. The fact that calcium still shows an (Ar) s^2 -ground-state configuration is due to the higher interelectronic repulsion exerted by the atomic field on an electron in a 3d orbital, compared with that exerted on an electron in a 4s orbital. The (Ar)sd state has thus a higher overall energy than the (Ar) s^2 state. The 3d orbitals play also a role in the Ca^{2+} ion, where they lie below the 4s orbitals by 2.2 eV. The marked particularities in catalytic behavior of potassium and calcium compounds, compared to their earlier homologues of sodium and magnesium, may thus well be explained on such grounds. The elements following calcium, i.e., scandium and titanium, have already an occupied 3d shell in their atomic ground state.

The chemical irrelevance of the 3d orbitals for elements with atomic numbers lower than or equal to 18 (Ar) is also emphasized by the results of scattering theory. S.T. Manson [13] of the American National Bureau of Standards calculated the electron scattering phase shifts as a function of electron energy and atomic number. He found that no appreciable phase shift is exerted on electronic d waves of low energy by the field of atoms with ordinal numbers lower or equal 18. This means that bonding interaction with 3d orbitals is energetically irrelevant for the elements preceding potassium! In a similar way, Manson shows that 4f orbitals

Table 2. Results of Herman-Skillman Calculations for the Elements Si to Ti. Orbital type (n,l), electronic occupation, orbital energy (E), and Slater exponent (ζ) are given for the indicated elements and configurations.

start to play a chemical role at earliest at atom number 55 (Cs) or 56 (Ba).

The '3d orbitals' used by R. Hoffmann *et al.* in their extended-Hückel calculations on Si, P, S, and Cl compounds can, therefore, by no means be real 3d orbitals. This is shown as well by the recommended parameter set for the ICON program (Table 1) [14], which deviates very much from what is obtained from atomic structure calculations (Table 2). The 'd orbitals' in Table 1 merely play a role as polarization functions, enlarging the basis set of the variational calculus and enabling the resulting wave-functions to get closer to the real molecular wave-functions. In this context, one could use, with equal success, double- or triple-zeta expansions for the second-row elements' s and p orbitals, because every additional component in the basis set, of any imaginable type, will enhance the accuracy of the variationally obtained molecular wave-functions. In a later paper, R. Hoffmann and coworkers explicitly discuss about the *deus ex machina* role that d functions were to play during some time in second-row elements' chemistry, concluding that such functions were at best useful as a calculation trick to enhance the precision of the EH energies [15].

But how to reply then to the more difficult arguments of *hypervalence* and *softness* of the second-row elements Si, P, S, and Cl?

- 1) *Hypervalence* is a concept formulated with respect to the VB formalism. It poses by no means a problem in the framework of quantum theory, in which the chemical bonding does not depend on the availability of a 2-electron orbital for every chemical bond of a molecule. The *pseudoproblem* of hypervalence can most easily be solved through a rigorous substitution of the somewhat ambiguous concept of 'valence' by the better defined concepts of 'oxidation state' and 'coordination number', along A. Werner's guidelines. The quantum-chemical requirement for a stable bonding situation is merely, that coordination geometry and electron configuration of a molecule are symmetry compatible.
- 2) *Softness* can be explained by the lower bond strengths of the bonds involving second-row elements, compared to bonds involving first-row elements. A low bond strength means, however, that the molecule has low-lying antibonding orbitals, or, in other words, remaining unsaturated valence! The bonds may easier be formed and broken in such a situation, and the atom

may also be involved into more bonds at a time. π -Acidity and backbonding in phosphines and thio-compounds are, therefore, rather tied to the presence of low-lying antibonding (σ^*) orbitals than to the presence of empty 3d orbitals. The observation of, *e.g.* a **lengthening** of the P-C bonds in alkyl- or arylphosphine complexes, in which the P-atom acts as a π -acid, could be a proof of this statement [16]. Such a lengthening would, in contrast, not occur in the case where the acceptor orbitals were phosphorus 3d orbitals.

Prof. Dr. Claude Daul, of the University of Fribourg, is cordially acknowledged for a copy of the *Herman-Skillman* Program as well as for advice concerning the exchange functional.
